Journal of Climate

EARLY ONLINE RELEASE

This is a preliminary PDF of the author-produced manuscript that has been peer-reviewed and accepted for publication. Since it is being posted so soon after acceptance, it has not yet been copyedited, formatted, or processed by AMS Publications. This preliminary version of the manuscript may be downloaded, distributed, and cited, but please be aware that there will be visual differences and possibly some content differences between this version and the final published version.

The DOI for this manuscript is doi: 10.1175/JCLI-D-14-00707.1

The final published version of this manuscript will replace the preliminary version at the above DOI once it is available.

If you would like to cite this EOR in a separate work, please use the following full citation:

Chen, H., and J. Sun, 2015: Changes in Drought Characteristics over China Using the Standardized Precipitation Evapotranspiration Index. *J. Climate*. doi:10.1175/JCLI-D-14-00707.1, in press.

1 **Abstract**

2 The Standardized Precipitation Evapotranspiration Index (SPEI) is computed and
3 compared in China using reference evapotranspiration calculated using the
4 Thornthwaite (TH) approach and the Penman-Monteith (PM) equation. The analysis
5 reveals that SPEI_PM outperforms the SPEI_TH with regard to drought monitoring
6 during the period 1961-2012 over China, especially in arid regions of China.
7 Furthermore, the SPEI_PM also performs better with regard to observed variations in
8 soil moisture and streamflow in China. Thus, changes in drought characteristics over
9 China are detected on the basis of variations in the SPEI_PM. The results indicate that
10 droughts over China exhibit pronounced decadal variations over the past 50 years,
11 with more frequent and severe droughts occurring before the 1980s and in the 2000s
12 compared with the 1980s and 1990s. Since the late 1990s, droughts have become
13 more frequent and severe across China, especially in some regions of northern China.
14 Concurrently, consecutive drought events have also increased across China. This
15 suggests that dry conditions in China have been enhanced in recent years. Further
16 analyses illustrate that the temperature and precipitation anomalies exhibit different
17 roles in detecting droughts across China, which is primarily due to the magnitude of
18 their variations and different climate variability. Considering temperature and
19 precipitation perturbations, droughts exhibit relatively larger responses to temperature
20 fluctuations in northern China and relatively larger responses to precipitation
21 anomalies in southern China.

1 **1. Introduction**

2 Drought is a major natural hazard that is characterized by below-average
3 precipitation over a long period of time. Droughts are recognized as one of the main
4 natural causes of agricultural, economic, and environmental damages. Moreover,
5 droughts occur over most parts of the world, even in humid regions. A large drying
6 trend can be observed over many land areas since the mid-1950s, with widespread
7 drying over much of northern Africa, Alaska, Canada, and Eurasia (Dai et al. 2004;
8 Dai 2012; Spinoni et al. 2014). Previous work has suggested that dry areas increased
9 by approximately 1.74% per decade from 1950 to 2008 (Dai 2011a). Many studies
10 have attributed most of this drying to the recent global warming (e.g., IPCC 2012).
11 The Fifth Assessment Report (AR5) of the Intergovernmental Panel on Climate
12 Change (IPCC) indicated that continued emissions of greenhouse gases would
13 definitely cause additional warming (IPCC 2013), enhancing dry conditions in the
14 future. Thus, a rising concern regarding this issue is common both within government
15 bodies and among the general public.

16 Due to the impacts of large-scale climate variability, including the East Asian
17 monsoon, China has suffered from several prolonging severe drought disasters that
18 have had major effects on some sectors, such as agriculture, industry, society and
19 ecosystems (Song et al. 2003; Zou et al. 2005; Ma and Fu 2006; Xin et al. 2006; Lu et
20 al. 2011; Wang et al. 2011; Yan et al. 2011; Wang et al. 2012; Liu and Jiang 2014).
21 Based on historical records, Zou et al. (2005) indicated that drought areas in North
22 China have significantly increase based on the Palmer Drought Severity Index (PDSI).
23 Yu et al. (2014) also revealed that severe and extreme droughts have become more
24 serious since the late 1990s in China and the dry areas was reported to increase by
25 ~3.72% per decade in the past five decades. In any particular year, there is typically a
26 region in China that endures a precipitation deficit and experiences drought, leading
27 to large societal and economic losses. The severe drought in 1997 over northern China
28 caused continuous zero flow in the Yellow River for nearly 226 days (Cong et al.

1 2009). Drought has also occurred in the Yangtze River basin, with runoff reached a
2 50-year low in 2006 (Yu et al. 2013). Both the long-term drought from autumn 2009
3 to spring 2010 across Southwest China and the short-term drought in July-August
4 2013 over the Jiangnan region (with air temperatures up to 42.7°C in Zhejiang
5 province) resulted in drinking water shortages for people and livestock and nearly no
6 crop harvest (Huang et al. 2012; Yang et al. 2012; Duan et al. 2013; Sun 2014). Such
7 severe droughts have been documented throughout the instrumental records and are
8 certain to continue in the future (Chen et al. 2013; Wang et al. 2014).

9 Because of the complexity of drought variability, it is challenging to objectively
10 quantify drought intensity, duration, and spatial extent (Dai 2011). Thus, numerous
11 studies have attempted to improve drought detection and monitoring; a few objective
12 indices have been developed on the basis of readily available data, such as
13 precipitation and temperature (e.g., Palmer 1965; Mckee et al. 1993; Ma and Fu 2001).
14 Among these indices, the PDSI, which is based supply and demand in the water
15 balance, is one of the most widely used drought indices around the world. However,
16 the PDSI has several deficiencies, including the strong influence of the calibration
17 period, the limitation in spatial comparative, and subjectivity in relating drought
18 conditions to the index values. Many of these problems were resolved with the
19 development of the self-calibrated PDSI (Wells et al. 2004); however, the main
20 shortcoming, i.e., the built-in fixed time scale (9-12 months), has not been resolved
21 (Guttman 1998). Based on the multi-scale characteristics of droughts, the
22 Standardized Precipitation Index (SPI), which is based on a probabilistic precipitation
23 approach, has been developed (McKee et al. 1993) and widely accepted in both
24 research and operational work in recent years (e.g., Gao and Yang 2009; Chen et al.
25 2013; Orłowsky and Seneviratne 2013). However, only the precipitation variability is
26 considered in the SPI calculation; the role of temperature is ignored. The effect of
27 temperature is evident in initiating droughts, although droughts are primarily caused
28 by below-average precipitation. Nevertheless, results from global climate model

1 simulations have indicated that drought induced by warming is well predicted using
2 the PDSI, while no expected changes are indicated using the SPI (Dubrovsky et al.
3 2008). Therefore, a new Standardized Precipitation Evapotranspiration Index (SPEI)
4 was developed by Vicente-Serrano et al. (2010) and further improved by Beguería et
5 al. (2013). This index is also based on the supply and demand concept of the water
6 balance equation. Thus, the SPEI not only considers the effects of temperature on
7 drought severity but also considers the multi-scale characteristics that are incorporated
8 in the SPI. Thus far, our understanding of global and regional drought conditions has
9 been primarily derived from variations in these drought indices.

10 The calculation of the SPEI is as simple as computing the SPI; however, the
11 water balance is represented by the difference between precipitation and
12 evapotranspiration (P-E) rather than only precipitation. Generally, the reference
13 evapotranspiration (ET) is calculated from temperature data using the empirical
14 Thornthwaite equation (TH; Thornthwaite 1948). However, many previous studies
15 have indicated that ET is underestimated in arid and semiarid regions (Jensen et al.
16 1990) and overestimated in humid regions (van der Schrier et al. 2011) using this
17 approach because ET is not solely determined by the ambient temperature. ET
18 calculations should include correct physics that account for radiative and aerodynamic
19 impacts (Roderick et al. 2007). Thus, the FAO (the Food and Agriculture Organization
20 of the United Nations) Penman-Monteith method (FAO PM), which is a more realistic
21 calculation that accounts for changes in available energy, humidity, and wind speed, is
22 recommended for computing ET (Allen et al. 1998). Furthermore, a few recent studies
23 have claimed that the drought indices provide better estimates of the true global
24 drought trend when using the PM evapotranspiration framework because of its more
25 comprehensive physics (Sheffield et al. 2012; Trenberth et al. 2014). Hence, the FAO
26 PM method will be included in the SPEI calculations. Moreover, a discussion of the
27 aridity changes in China using updated data from 1960 to 2012 will be provided in
28 this study, further improving our understanding of warming-induced drought changes

1 in China.

2

3 **2. Data and methods**

4 *a. Data*

5 First, the SPEI is determined using two different reference evapotranspiration
6 calculations, i.e., the empirical Thornthwaite equation (SPEI_TH) and the more
7 sophisticated Penman-Monteith method (SPEI_PM). The PM equation requires
8 extensive amounts of data, including solar radiation, temperature, wind speed, and
9 relative humidity. These monthly datasets (in addition to precipitation data) are
10 collected for the period 1951-2012 from the National Meteorological Information
11 Center of the China Meteorological Administration (CMA) based on observations
12 from 756 meteorological stations. The homogeneity and reliability of these monthly
13 meteorological datasets have been checked and firmly quality controlled before being
14 release. Although these datasets have been available since 1951, there are many
15 missing data in the 1950s over most of China. Thus, the target period in this study is
16 from 1960 to 2012. Based on the data for these 53 years, if a given site is missing 5%
17 of the time series, the site is rejected. Accordingly, a subset of 564 stations is selected
18 and there are 80 sites still have missing records. These missing monthly records are
19 replaced by the climatological values for the period 1960-2012. The locations of these
20 meteorological stations are shown in Figure 1.

21 Three additional monthly datasets are also used in this study to compare with the
22 SPEI_TH and SPEI_PM trends, including site-observed soil moisture, streamflow,
23 and the self-calibrated PDSI. First, the monthly soil moisture (m^3/m^3) data are
24 collected from CMA based on observations at 226 meteorological stations in China;
25 the dataset consists of information for the top-10 cm, 20 cm, and 50 cm layers and
26 encompasses the period 1993-2008. Second, the observed monthly streamflow data
27 during the period 1962-2000 from Harbin station, which is located in the Songhua
28 River basin of northeastern China. Third, the PDSI data used in this study are the

1 monthly self-calibrated PDSI values using the more sophisticated PM equation to
2 estimate the potential evapotranspiration (scPDSI_PM); the PDSI data based on
3 historical data (Dai 2011b), which have been updated for the period 1850-2012.

4 Due to the large area of China, the Chinese climate is very complex and varies
5 substantially from region to region. According to annual precipitation data, China can
6 be divided into four climatic regions: arid, semi-arid, semi-humid, and humid regions
7 (Figure 1). The arid climate dominates most of northwestern China, with annual
8 precipitation amounts of less than 200 mm. The semi-arid and semi-humid regions
9 exhibit annual precipitation amounts ranging from 200 to 400 mm and from 400 to
10 800 mm, respectively. The climate in the humid region, which is primarily confined to
11 southern China, is much wetter, with annual precipitation amounts exceeding 800 mm
12 (Zheng et al. 2013). Climate changes are generally different among these regions;
13 therefore, drought variabilities are discussed in this study. Among the 564 stations,
14 there are 66 stations in the arid region, 70 in the semi-arid region, 177 in the
15 semi-humid region and 251 in the humid region, respectively. Additionally, China is
16 divided into eight sub-regions, including Northeast China (NEC), North China (NC),
17 Huang-Huai basin (HH), Jiangnan (JN), South China (SC), Southwest China (SWC),
18 Northwest China (NWC) and Neimeng (NM); these regions are used in the following
19 discussion. These divisions are based on the China meteorological and geographical
20 division handbook that was released by the National Meteorological Center of the
21 CMA in 2006; this information can also be found in other studies (e.g., Chen et al.
22 2012a).

23 24 ***b. Calculation of ET***

25 Two methods are used to calculate ET in this study.

26 First, the simple Thornthwaite approach (Thornthwaite 1948) is used to calculate
27 ET, which is advantageous because the method only requires monthly temperature
28 data:

$$ET = 16K\left(\frac{10T}{I}\right)^m, \quad (1)$$

where T is the monthly mean temperature (°C); I is the heat index, which is calculated from the monthly temperature; m is a coefficient depending on I; and K is a correction coefficient that is computed as a function of the latitude and month.

ET is also computed using the sophisticated Penman-Monteith method (Allen et al. 1998), which is based on underlying physical principles and accounts for both thermodynamic and aerodynamic effects:

$$ET = \frac{0.408\Delta(Rn - G) + \gamma(900 / (T + 273))U_2(e_s - e_a)}{\Delta + \gamma(1 + 0.34U_2)}, \quad (2)$$

where Δ is the slope of the saturation vapor pressure curve (kPa °C⁻¹); Rn is the net radiation (MJ m⁻² day⁻¹); G is the soil heat flux density, which is considered to be 0 for daily estimates; T is the daily mean air temperature (°C) at a height of 2 m, which is based on the average of the observed maximum and minimum temperatures; U₂ is the averaged wind speed at a height of 2 m (m s⁻¹); e_s is the saturation vapor pressure (kPa); e_a is the ambient vapor pressure (kPa); (e_s-e_a) is the saturation vapor pressure deficit at temperature T; and γ is the psychrometric constant (0.0677 kPa °C⁻¹).

There are no available solar radiation data from the meteorological stations in China; therefore, an empirical formulation recommended by Allen et al. (1998) is used here to calculate the net radiation based on the observed number of sunshine hours. The saturation vapor pressure deficit is determined based on the relative humidity and the maximum and minimum temperatures. Additionally, assuming a logarithmic wind speed profile, the observed wind speed at a height of 10 m is converted to the standard height of 2 m for use in the aforementioned calculation. For more approximations and details please refer to Sentelhas et al. (2010).

Before calculating the SPEI, the differences in Penman-Monteith and Thornthwaite evapotranspiration are analyzed (Figure not shown). Results indicate that the ET_{PM} shows relatively greater, by 20% or more, over most regions of northern China and Southwest China than ET_{TH}. However, over most regions of

1 southern China and Northeast China the ET_PM is relatively less than ET_TH. These
2 results agree well with early studies (Jensen et al. 1990; van der Schrier et al. 2011).

3 Then, the SPEI_TH and SPEI_PM are calculated at different time scales for each
4 station based on the accumulated deficit and surplus, that is, the climate water balance
5 (P - E). This computation is the same procedure used to determine the SPI; more
6 information can be found in Vicente-Serrano et al. (2010). Table 1 shows the
7 categorization of dryness/wetness grade according to the SPEI and the corresponding
8 cumulative probability in relation to the base period.

9

10 *c. Analysis methods*

11 The greatest advantage of the SPEI is its representation of multiple time scales,
12 which allows monitoring of different drought types, such as meteorological,
13 agricultural, hydrological, and societal drought. In this study, the drought
14 characteristics represented by the SPEI with 3- and 12-month scales are primarily
15 investigated, including the area, frequency, and intensity. Before calculating the
16 drought area, the site-specific SPEI is resampled to $0.5^{\circ} \times 0.5^{\circ}$ grids (longitude by
17 latitude) using the inverse distance weighting interpolation method. Then, the drought
18 area is computed as the sum of the weighted (cosine function of latitude) grid area for
19 the $SPEI < -1.0$. The drought frequency is simply defined as the number of months in
20 which the $SPEI < -1.0$; the corresponding mean SPEI value is the intensity.
21 Additionally, the variations in consecutive dry events (at least six months) are also
22 investigated. To analyze the drought characteristic variations in China, Sen's slop
23 method (Sen 1968) is used in this study to calculate the linear trend; the
24 nonparametric Mann-Kendall (MK) approach is applied for its significance test.

25

26 **3. Comparison of the SPEI_PM to SPEI_TH for monitoring drought in China**

27 Previous studies have documented that there is nearly no difference between the
28 SPEI_PM and SPEI_TH for monitoring drought in some regions, especially from a

1 global perspective (e.g., Beguería et al. 2013). Is this true in China? This question has
2 not been answered; therefore, the focus of this study is to address this question.

3 Figure 2 shows the spatial patterns of the MK trend statistics for the annual
4 precipitation, SPEI_TH, SPEI_PM, and scPDSI_PM in China for the period
5 1961-2012. The positive and negative values represent trends toward wetter and drier
6 conditions, respectively. Based on Figure 2(a), the annual precipitation changes in
7 China exhibit large regional differences over the past 50 years, with significant
8 upward (wetting) trends over NWC, eastern Tibet, and the coastlines of JN and SC
9 and significant downward (drying) trends over western NC and eastern SWC. Here, a
10 significant trend means that it passed the MK test at the 5% and 10% significance
11 levels. The wetting trend in NWC is consistent with the recent study by Chen et al.
12 (2012b), who indicated that NWC has experienced a remarkable wet shift since the
13 mid-1980s.

14 Similarly, Figure 2(b) presents the variations in the spatial patterns of the annual
15 SPEI_TH. Significant drying trends are found for most regions in China; significant
16 wetting trends are detected over only a few stations in Xinjiang, coastal eastern China,
17 and SWC. The variations in the annual SPEI_PM exhibit much larger differences than
18 the SPEI_TH, especially over NWC (Figure 2c). Similar to the annual precipitation
19 changes, the annual SPEI_PM exhibits significant trends toward wetter conditions
20 over most stations in NWC. Although there are no pronounced annual precipitation
21 changes over NEC, NM, and eastern NC, the variations in both the annual SPEI_TH
22 and SPEI_PM consistently exhibit drying trends over the past 50 years. However,
23 more stations experiencing significant drying trends at the 95% confidence level are
24 found in the SPEI_TH than in the SPEI_PM. The drying conditions over western NC,
25 eastern NWC, and eastern SWC are well captured by both the SPEI_TH and the
26 SPEI_PM, although more stations exhibit significant trends according to the
27 SPEI_TH. Significant trends toward wetter conditions are detected over some small
28 areas in JN and SC according to the SPEI_TH, while larger areas are reported using

1 the SPEI_PM. The annual SPEI_TH changes exhibit no obvious trends in HH, while
2 significant wetting trends are detected by the SPEI_PM. The SPEI_PM changes in
3 this region are much more realistic than that of the SPEI_TH because the rain belt has
4 been observed to experience a northward shift since 2000 (Si et al. 2009; Zhu et al.
5 2011).

6 To further validate the performance of the SPEI_TH and the SPEI_PM, the
7 spatial distribution of the MK trend statistic for the annual scPDSI_PM is also
8 presented for China (Figure 2d). Clearly, significant trends toward wetter conditions
9 are also detected over western China and some coastal areas of eastern China;
10 significant downward trends are found in the other regions. This spatial pattern of
11 scPDSI_PM changes is similar to that of the annual precipitation and the SPEI_PM,
12 while there are some discrepancies with the SPEI_TH in some regions, especially
13 over western China.

14 Based on the above analysis, we can conclude that the effect of temperature
15 changes is amplified in the SPEI_TH with regard to monitoring drought over China.
16 Particularly over NWC, where the annual precipitation is less than 200 mm, the
17 drying trends in the annual SPEI_TH are primarily attributed temperature increases.
18 Thus, the wet shift in the mid-1980s cannot be captured by the SPEI_TH. When the
19 more realistic reference evapotranspiration calculation is used, the role of temperature
20 changes is restrained because wind speeds and vapor pressure deficits are also
21 considered. This is especially true in the arid regions of China. However, only a slight
22 difference between SPEI_TH and SPEI_PM is found in the humid regions because
23 there is enough precipitation in this region for evapotranspiration to occur and nearly
24 no difference in the variations of P - E (Figure not shown).

25 The changes in the annual SPEI_TH and SPEI_PM are also compared with soil
26 moisture variations in different layers. Figure 3(a) presents the spatial distribution of
27 the site-observed soil moisture (top 10-cm layer) over China for the period 1993-2008.
28 Significant wetting trends can be seen over most of NWC, NC, HH, and Tibet, while

1 significant drying trends are well defined over some areas of NEC and NM. The
2 SPEI_TH (Figure 3b) and the SPEI_PM (Figure 3c) both depict significant drying
3 trends for most stations over NWC, although the SPEI_PM captures wetting trends
4 for some stations in this region. Additionally, the wetting trends over some stations in
5 NC, HH, and southern NEC represented in the soil moisture data are well monitored
6 by the SPEI_PM but not by the SPEI_TH. Similar results can be obtained based on
7 soil moisture changes in the other two studied layers.

8 The SPEI_PM also performs better at monitoring streamflow variations than the
9 SPEI_TH. Despite the high correlations between the streamflow and the two SPEIs
10 (0.56 for the SPEI_TH and 0.59 for the SPEI_PM, respectively), the increasing trend
11 in the streamflow is only captured by the SPEI_PM; the SPEI_TH exhibits a
12 decreasing trend. However, there are some uncertainties regarding this result due to
13 data limitations; more materials are needed for further verification in the future.

14 Briefly, the SPEI_PM is much better for monitoring drought over China than the
15 SPEI_TH, particularly over the arid regions. Therefore, the changes in drought
16 characteristics over China during the past 50 years are investigated in the following
17 section using the SPEI_PM.

18

19 **4. Drought changes over China**

20 Figure 4 presents the temporal variations in drought area in China during the
21 period 1961-2012. The drought area in China exhibits a well-defined interdecadal
22 shift according to the SPEI_PM, with a relatively large dry area before the 1980s and
23 from the late 1990s to the present and a relatively small dry area from the mid-1980s
24 into the 1990s. Based on a comparison of the drought areas during the two dry periods,
25 we find that the current dry conditions in China are not as intense as the earlier period;
26 moreover, the strongest dry conditions occurred primarily in the 1960s. Similar
27 variations in drought area are observed in different levels of drought severity.

28 The temporal variations in drought area over arid, semi-arid, semi-humid, and

1 humid regions in China are shown in Figure 5. Similar characteristics in the drought
2 area variations are found for these four regions, i.e., a relatively large dry area was
3 present in the 1960s, 1970s, early 1980s, and since the late 1990s, while a relatively
4 small dry area was present from the mid-1980s into the 1990s. However, there are
5 some well-defined differences among these regions. For the arid region, vast drought
6 events occurred primarily in the 1960s and the 1970s. Despite an increase in drought
7 area in the 2000s compared to the 1990s, the current drought area remains much
8 smaller than that in the 1960s and the 1970s. Drought area changes in the semi-arid
9 region are similar to that of the arid region, while relatively large differences are
10 found when comparing both the semi-humid and humid regions to the arid and
11 semi-arid regions. For the semi-humid region, the drought area increased significantly
12 beginning in the late 1990s and the variations in drought area are comparable to the
13 1960s and the 1970s. Furthermore, extensive droughts have occurred more frequently
14 since the late 1990s when compared to earlier periods in this region. The drought area
15 in the humid region has also exhibited significant increases since the late 1990s; the
16 drought that occurred from winter 2011 to spring 2012 across Southwest China,
17 including Yunnan, Guangxi, Guizhou, Sichuan, and Chongqing provinces, was the
18 largest drought over the previous 50-year period. Nevertheless, the frequency of
19 droughts has increased. Briefly, drought areas have dramatically increased since the
20 late 1990s in both the humid and semi-humid regions, while smaller changes are
21 detected in the arid and semi-arid regions.

22 Based on the above analysis, a significant decadal change in drought area has
23 occurred during recent decades in both China and its associated sub-regions. To better
24 understand the dry conditions in China, the characteristics of the decadal changes in
25 drought events are investigated for two dry periods (i.e., 1970-1980 and 2000-2010)
26 and a wet period (i.e., 1985-1995). Figure 6 shows the spatial patterns of the decadal
27 changes in drought frequency, which are represented by the monthly number of
28 occurrences in which the SPEI < -1.0 in China. In the period 1985-1995, the drought

1 frequency decreased over most of China when compared to the earlier period,
2 especially in northern China, including stations in NWC, NC, NM, and NEC. A
3 decrease also occurred for most stations in eastern Tibet. However, several sparse
4 stations in SC and eastern SWC have suffered from increasing drought frequency.
5 These changes reversed in the early portion of the current century; the drought
6 frequency began to increase over most areas of China. In NC and NEC, the drought
7 frequency increased substantially for a few stations during the period 2000-2010
8 relative to the period 1985-1995; however, drought events at sparse stations in NWC
9 have continued to decrease in recent years. Relatively small changes are found for the
10 stations over eastern China; however, significant decadal changes are observed in this
11 region, with more drought events occurring during the periods 1970-1980 and
12 2000-2010 and less occurring during the period 1985-1995. Additionally, the annual
13 cycles of the droughts in China also vary from decades and regions. In 2000-2010,
14 droughts over NEC and NM mainly occur in boreal autumn and droughts over NWC
15 prevail in spring and summer. Over most regions of eastern China, including NC, HH,
16 and JN, droughts mainly happen in spring and early summer (Figure not shown).

17 The decadal changes in drought frequency in the arid, semi-arid, semi-humid,
18 and humid regions (Figure 7) reveal that the minimum drought frequency occurred
19 during the period 1985-1995 in these four regions and for all of China. In the arid
20 region, droughts were more common during the period 1970-1980, with relatively few
21 incidents in recent years. In the semi-arid and semi-humid regions, droughts occurred
22 with similar frequencies during the periods 1970-1980 and 2000-2010, with a much
23 higher frequency of occurrence compared with the period 1985-1995. However, the
24 changes in the humid region are different. The drought frequencies during the periods
25 1985-1995 and 1970-1980 are comparable, with less drought events occurring in this
26 region. However, a relatively high drought frequency is found for the period
27 2000-2010 in the humid region, which indicates that the dry conditions over most of
28 China have been enhanced during the most recent decade, especially in the humid

1 region.

2 In addition to changes in drought frequency, variations in drought intensity were
3 also investigated over China. Figure 8 illustrates the spatial distributions of the
4 decadal changes in drought intensity (mean values of the SPEI < -1.0) over the past
5 several decades. Clearly, the spatial patterns of changes in drought intensity are
6 similar to those of drought frequency. The regions with decreases in drought
7 frequency are generally accompanied with a reduction in drought intensity (and vice
8 versa). During the period 1985-1995, the drought intensity was much weaker over
9 most of China compared to the period 1970-1980. However, the intensity increases
10 during the period 2000-2010 in most regions of China, particularly at stations in NEC,
11 NC, HH, NM and NWC. This result further demonstrates that the dry conditions in
12 China have been enhanced in recent years, especially in northern China. This result is
13 further validated by the temporal variations in drought intensity (Figure 9). Two
14 drought intensity peaks have occurred during past 50 years for each sub-region and
15 for all of China. The results indicate that the droughts in China were relatively severe
16 during the 1960s, 1970s and 2000s and relatively weak during the 1980s and 1990s.
17 Similar characteristics can be seen for the four sub-regions, particularly for the arid
18 region, which has exhibited a relatively large change in drought intensity during
19 recent decades.

20 Based on the spatial distribution of drought duration for China during the period
21 1961-2012, which is defined as the longest number of consecutive months in which
22 the 3-month SPEI < -1.0, some portions of NWC, NEC, NC, NM and SWC
23 experienced droughts exceeding 12 months in duration, with some even exceeding 18
24 months at stations in Xinjiang province. According to the available data, the most
25 severe droughts in 2009/2010 and 2011/2012 across SWC (including Yunnan, Sichuan,
26 Guizhou, Guangxi, and Chongqing provinces) exhibited the longest duration
27 compared with other drought events during recent decades. Consecutive drought
28 events generally cause relatively large effects on agriculture, ecosystems and society.

1 Thus, the decadal variations in the frequency and intensity of consecutive drought
2 events, which are defined based on events in which the SPEI_PM < -1.0 (using a
3 3-month scale) for at least six months, are presented in Figure 10. A reduction in the
4 number of consecutive drought events is found over China for the period 1985-1995
5 when compared with the period 1970-1980; some stations exhibit decreases exceeding
6 2 events, especially in NWC. However, during the period 2000-2010, this decrease
7 ended and was followed by an increase in the occurrence of consecutive drought
8 events at most stations across China. Based on the analysis of intensity changes, a
9 significant increase in the intensity of the consecutive drought events has occurred in
10 recent years. Furthermore, for some stations across China, no consecutive drought
11 events occurred in the early period (1985-1995), while such events occurred,
12 sometimes exceeding 2 events, during the period 2000-2010. These results
13 demonstrate that the dry conditions have been enhanced in recent years across most of
14 China; this drying trend will intensify with continued warming in the future.

15 The aforementioned analyses reveal that droughts in China have featured a
16 significant interdecadal variation over the past 50 years and that these events have
17 become more frequent and severe in most regions of China in recent years.
18 Correspondingly, the associated dry conditions have been enhanced. These results are
19 very important and valuable to both the public and government; more attention to this
20 topic is needed.

21

22 **5. Responses to precipitation and temperature changes**

23 The SPEI_PM measures the accumulated effect of a deficit/surplus in the water
24 balance between the actual monthly precipitation and the required precipitation. The
25 required precipitation is generally a function of air temperature. Thus, variations in
26 the SPEI_PM primarily include effects from precipitation and air temperature
27 anomalies. Several studies have revealed the influences of temperature and
28 precipitation anomalies on the PDSI and other related indices (e.g., Guttman 1991; Hu

1 and Willson 2000). For example, previous results have indicated that precipitation
2 anomalies tend to dominate changes in the PDSI during the cold season due to the
3 inherent evaporation minimum during this season, while the ambient temperature
4 becomes important for the PDSI in the warm season. However, such analysis has not
5 been applied to the SPEI_PM. Moreover, the precipitation and temperature effects on
6 the SPEI_PM have not been thoroughly investigated thus far.

7 Several experiments are used to illustrate the effects of precipitation and
8 temperature, including scenario 1, in which the temperature is assumed to increase
9 progressively by 2°C, while the actual precipitation variability for each month is
10 based on observations from 1961 to 2012; scenario 2, in which the precipitation is
11 increased progressively by 10%, while the actual temperatures are used; and scenario
12 3, in which the temperature increases progressively by 2°C in conjunction with a
13 continuous increase in precipitation of 10%. The SPEI_PM is recalculated after
14 adding these perturbations to the monthly temperature and precipitation data,
15 respectively. Additionally, the SPEI_PM is also calculated using the historical data to
16 provide a basis for comparison and to identify the responses of the SPEI_PM to
17 temperature and precipitation changes.

18 Figure 11 shows the spatial patterns for the relative changes in drought frequency
19 and intensity for the three perturbation scenarios relative to the real climate conditions.
20 In scenario 1, which experiences a progressive temperature increase of 2°C, droughts
21 increase significantly across China over the last two decades, with a relatively large
22 increase in northern China and a smaller increase in southern China. The average
23 drought frequency in China increases by 19%; however, the increase varies regionally.
24 The largest increase occurs in the arid region (by 53%), which is followed by the
25 semi-arid and semi-humid regions (by 20%) and the humid region (by 9%).
26 Additionally, for the case in which the temperature progressively increases by 2°C,
27 the drought severity is reinforced due to the high water demand of PET (based on the
28 SPEI_PM), with drought intensity increasing across China. The average drought

1 intensity in China increases by 13%. The changes in drought severity are similar to
2 those of drought frequency, with a relatively large increase in drought severity in the
3 arid region (by 31%), which is followed by the semi-arid and semi-humid regions
4 (14%), and the humid region (7%). This finding suggests that if precipitation remains
5 constant, the ambient temperature will play a major role in determining future drought
6 severity in China, which is consistent with the results of previous studies (e.g.,
7 Vicente-Serrano et al. 2010; Chen and Sun 2015).

8 If the precipitation is increased progressively by 10% (scenario 2), the drought
9 response is opposite that of increasing the air temperature, i.e., droughts are mitigated
10 across China. However, a relatively large response in the SPEI_PM to increased
11 precipitation is found in southern China, while a relatively small response occurs in
12 the other regions. Same result is also applied to drought severity across China. This
13 conclusion may be partially associated with the relatively large increase in
14 precipitation (i.e., 10%) in southern China, leading to relatively large precipitation
15 variability compared with the other regions. Considering China as a whole, drought
16 frequency decreases by 11% and the corresponding drought intensity decreases by 9%
17 if the precipitation increases by 10%. For the arid region, relatively small responses
18 are found at most stations, except for several stations in northern Xinjiang province.
19 The average frequency and intensity in this region decrease by 4% and 3%,
20 respectively. The responses in the semi-arid and semi-humid regions are much larger,
21 i.e., the frequency and intensity decrease by 9% and 8%, respectively. The most
22 noticeable changes occur in the humid region, in which the frequency and intensity of
23 droughts decrease by 14% and 11%, respectively.

24 Based on the aforementioned analyses of scenario 1 and scenario 2, a spatial
25 inhomogeneity is present in the response of the SPEI_PM to temperature and
26 precipitation perturbations; this response varies regionally because of local variations
27 in total precipitation amounts. In the humid region, there is enough precipitation to
28 meet the high water demand of PET; this is true even if the air temperature is assumed

1 to increase significantly. Thus, the responses in this region are relatively large for
2 precipitation changes compared with temperature changes. However, this result is
3 reversed in the other regions in China, especially in the arid and semi-arid regions.
4 This difference is because there is not enough precipitation to meet the water demand
5 of PET, which is true even if the local precipitation is assumed to increase
6 significantly. Thus, droughts in these regions exhibit greater sensitivity to temperature
7 changes than to precipitation changes. To further illustrate this point, another
8 experiment is performed, namely scenario 3. In this scenario, drought frequency
9 decreases substantially in the humid region (by 6%) and increases in the other regions
10 (by 47% in the arid region and by 10% in the semi-arid and semi-humid regions).
11 Similar changes are found for drought intensity, i.e., a decrease of 5% in the humid
12 region and an increase of 27% in the arid region and 7% in the semi-arid and
13 semi-humid regions.

14 Based on the above analyses, the SPEI_PM exhibits different responses to
15 temperature and precipitation anomalies that vary regionally across China. Relatively
16 large responses in droughts to temperature perturbations occur primarily over northern
17 China, while large responses to precipitation anomalies are found over southern China.
18 These results may be associated with the assumed extent of the temperature and
19 precipitation changes. Therefore, experiments in which the temperature is increased
20 by 4°C and the precipitation is increased by 20% are also explored; the results are
21 similar to those of aforementioned scenarios except that the response is stronger, i.e.,
22 approximately doubled.

23 However, another important question is raised: what are the actual roles of
24 temperature and precipitation variations in drought changes over China during recent
25 decades? This is a complicated question to answer because of the nonlinear
26 interactions among temperature, precipitation, and drought. Here, we attempt to
27 address this question via sensitivity experiments by assuming a linear relationship
28 among the effects of several factors (e.g., precipitation, temperature, and wind) on

1 droughts in China. The experiments are designed as follows. Experiment 1 assumes
2 that the air temperatures remain constant based on the values in 1960 for each month;
3 no changes are applied to the other factors. Experiment 2 applies the same assumption
4 to precipitation variations. The SPEI_PM is recalculated on the basis of these datasets.
5 The approximate roles of temperature and precipitation anomalies on droughts can be
6 estimated from the difference between the real climate conditions and these two
7 experiments. The corresponding results for the changes in drought frequency and
8 intensity due to temperature and precipitation variations during the last two decades
9 are shown in Figure 12. The temperature variations over recent decades exhibit
10 relatively large positive effects on the occurrence of drought over northern China,
11 including Tibet, while relatively small effects are found over southern China. The
12 results indicate that approximately 42% of the observed droughts have been caused by
13 temperature anomalies over the last two decades in the arid region; this proportion
14 decreases to approximately 22% for the semi-arid and semi-humid regions and only 5%
15 for the humid region. Similar magnitudes are found for the effects on drought severity,
16 i.e., approximately 45% in the arid region, 22% in the semi-arid and semi-humid
17 regions, and 5% in the humid region. This spatial inhomogeneity of the temperature
18 effects may be interpreted via two causes. One cause is the spatial inhomogeneity of
19 the total precipitation amount in China (as discussed above in this section). The other
20 cause is the spatial inhomogeneity of the temperature increase during recent decades,
21 with a relatively large increase over northern China and Tibet and a small increase
22 over southern China. The results are different when considering precipitation
23 variations during recent decades. Droughts are found to decrease in China due to the
24 precipitation variations, especially over some parts of southern China, North Xinjiang,
25 and Tibet. Moreover, the drought severity decreases over southern China and some
26 parts of North and Northeast China because droughts are primarily modulated by
27 precipitation variations in these regions (the precipitation amounts are sufficient to
28 meet the water demand of PET). The drought severity is mitigated by approximately

1 35% in the humid region compared to the experiment in which precipitation remains
2 constant, approximately 21% in the semi-arid and semi-humid regions, and 9% in the
3 arid region. Additionally, the drought occurrences decrease by approximately 10%,
4 7%, and 5% in the arid, semi-arid and semi-humid, and humid regions, respectively,
5 due to the effects of precipitation variations in recent decades.

6

7 **6. Conclusions and discussion**

8 There are vast differences in the annual accumulated potential evapotranspiration
9 between Thornthwaite (1948) parameterization and the FAO-endorsed
10 Penman-Monteith parameterization (Allen et al. 1998) estimates. Although some
11 studies (e.g., Beguería et al. 2013) have documented that these methods produce
12 similar estimates of the SPEI from global perspective, several pronounced differences
13 are found when focusing solely on China, especially in its arid regions. The effects of
14 temperature changes on drought characteristics are generally amplified in the arid
15 region of China when ET is calculated according to the Thornthwaite approach.
16 However, the results from the SPEI_PM, in which ET is calculated using the more
17 realistic PM equation, are more reasonable and better reflect climate change
18 conditions in this region. Nevertheless, the site-observed soil moisture and streamflow
19 variations are also used in this study for additional comparisons with regard to the
20 performance of the SPEI_TH and the SPEI_PM. Because the SPEI_PM is more
21 robust than the SPEI_TH, the SPEI_PM is recommended for investigating changes in
22 drought characteristics over China based on updated data covering the period
23 1961-2012.

24 Changes in several drought characteristics are investigated based on data for the
25 past 50 years, including drought frequency, intensity, and percentage of area affected.
26 The results indicate that droughts over China exhibit a well-defined decadal variation
27 during the past 50 years, with more frequent droughts occurring before the 1980s and
28 in the 2000s and fewer droughts in the 1980s and the 1990s. Based on changes in

1 drought area, several regional differences are detected. The drought area is found to
2 have increased since the late 1990s in the arid and semi-arid regions; the increase was
3 much smaller in the 1960s and the 1970s. Moreover, the increases in the semi-humid
4 and humid regions are found to be more substantial, especially in the humid region,
5 which is where several extensive droughts have recently occurred. The analysis also
6 reveals that droughts in China have become more frequent and severe in the recent
7 decade, which is concomitant with a significant increase in consecutive drought
8 events. This finding suggests that the dry conditions across China have been enhanced
9 in recent years, particularly for some stations in northern China that have experienced
10 relatively large increase in both drought frequency and severity.

11 Further analyses illustrate that temperature and precipitation changes exhibit
12 different roles in determining droughts in China; these different roles are primarily
13 related to the extent of the changes and different climate variability. When
14 temperature and precipitation perturbations are added to the data, respectively,
15 different drought responses are observed. The responses in the SPEI_PM to
16 temperature and precipitation anomalies vary regionally across China. Relatively
17 large responses to temperature changes are found over northern China, especially in
18 the arid region, while relatively small responses occur in southern China, especially in
19 the humid region. The opposite shifts are found in response to precipitation
20 perturbations, with relatively large responses in southern China and small response in
21 northern China. This spatial inhomogeneity in the responses is partially associated
22 with the local variations in total precipitation amounts. These results are also true for
23 the real climate conditions. The actual temperature anomalies during recent decades
24 exhibit larger contributions to the occurrences of drought over northern China, while a
25 smaller contribution is found over southern China. Temperature contributions are
26 found to cause approximately 42%, 22%, and 5% of droughts in the arid region, the
27 semi-arid and semi-humid regions, and the humid region, respectively. The actual
28 precipitation anomalies exhibit relatively large effects on drought severity compared

1 with drought occurrences, with a large contribution in the humid region (35%), which
2 is followed by the semi-arid and semi-humid regions (21%) and the arid region (9%).
3 Based on these experiment analyses, we can conclude that the rapid warming of China
4 in recent decades presents a relatively greater role in determining droughts than that
5 of precipitation variations. However, more validations are still needed.

6 Changes in drought characteristics during the past 50 years in China are detected
7 and analyzed in this study; however, the mechanism for these changes remains
8 unknown due to the complexity of drought occurrences (Dai 2011a). Thus far, some
9 studies have shown that wet-dry variations in northern China are statistically related
10 to the phase transition of the Pacific Decadal Oscillation (PDO) (e.g., Ma 2007);
11 however, it is uncertain if this change is related to natural variability or anthropogenic
12 changes. Additionally, the droughts in the humid region (especially in SWC) have
13 increased substantially and have become much more severe in recent years. A possible
14 mechanism for the specified drought events that have recently occurred has been well
15 addressed in this region, particularly in SWC (e.g., Yang et al. 2011). However, a
16 mechanism for explaining the recent drying trend remains unknown. More studies are
17 needed to address these issues in the future and to improve our understanding of
18 drought changes in China.

1 **Captions:**

2 **Table 1.** Categorization of dry and wet grade according to the SPEI and the
3 corresponding cumulative probability relative to the base period.

4 **Fig. 1.** Locations of the 564 meteorological stations in China and the associated eight
5 sub-regions (NEC: Northeast China; NC: North China; HH: Huang-Huai basin; JN:
6 Jiangnan; SC: South China; SWC: Southwest China; NWC: Northwest China; and
7 NM: Neimeng); the arid, semi-arid, semi-humid, and humid regions are also depicted.

8 **Fig. 2.** Spatial distributions of the MK trend statistic for the (a) annual precipitation,
9 (2) annual SPEI_TH (12 month), (c) annual SPEI_PM (12 month), and (d) annual
10 scPDSI_PM based on the period 1961-2012. The significance levels of 5% and 10%
11 are shown, respectively.

12 **Fig. 3.** Trend variations in the (a) annual soil moisture in the top 10-cm layer, (b)
13 annual SPEI_TH (3 month), and (c) annual SPEI_PM (3 month) for the period
14 1993-2008.

15 **Fig. 4.** Temporal variations in the monthly area coverage (in %) for (a) moderate, (b)
16 severe, and (c) extreme drought conditions in China. The drought areas are calculated
17 based on the 12-month SPEI_PM. The time periods denoted by the dashed lines are
18 discussed in this study.

19 **Fig. 5.** Temporal variations in the monthly area (in %) of drought conditions in which
20 the 12-month SPEI_PM < -1.0 in China during the period 1961-2012. (a) The arid
21 region, (b) the semi-arid region, (c) the semi-humid region, and (d) the humid region
22 are shown.

23 **Fig. 6.** Spatial distributions of the decadal variations in drought frequency (3-month
24 SPEI_PM < -1.0) over China during recent decades. (a) The drought frequency
25 difference between the period 1985-1995 and the period 1970-1980, (b) difference
26 between the period 2000-2010 and the period 1985-1995. The symbol × indicates that
27 the differences are significant at the 95% confidence level using a t-test.

28 **Fig. 7.** Drought frequency distributions for different regions in China. (a) China, (b)

1 the arid region, (c) the semi-arid region, (d) the semi-humid region, and (e) the humid
2 region are shown.

3 **Fig. 8.** Same as in Figure 6 but for drought intensity changes.

4 **Fig. 9.** Decadal variations in drought intensity for different regions in China. A 21-yr
5 low-pass filtering process was used for each series.

6 **Fig. 10.** Decadal variations in the frequency of consecutive drought events (defined as
7 those events in which the 3-month SPEI_PM < -1.0 for at least six months). (a)
8 Differences between the period 1985-1995 and the period 1970-1980. (b) Differences
9 between the period 2000-2010 and the period 1985-1995.

10 **Fig. 11.** Spatial patterns in the responses of drought (3-month SPEI_PM < -1.0)
11 frequency (left column) and intensity (right column) to temperature and precipitation
12 changes. The top panels show the responses of drought frequency (a) and intensity (d)
13 to temperature changes (progressive increase of 2°C) when actual precipitation
14 variability is used for each month between 1961 and 2012. The middle panels (b and e)
15 depict the results for increased precipitation (by 10%). The bottom panels (c and f)
16 depict the results in which both the precipitation and temperature are perturbed over
17 the same period. The response is defined as the relative change compared to the
18 results based on the original SPEI_PM during the period 1993-2012.

19 **Fig. 12.** Responses of drought to real temperature and precipitation changes during
20 recent decades. (a and c) The relative changes in drought frequency and intensity,
21 respectively, due to real temperature changes. (b and d) The results due to real
22 precipitation changes. Here, the response is defined as the relative difference between
23 the real climate conditions and the experiments in which the temperature and
24 precipitation are assumed to remain constant for the entire analysis period based on
25 the values for each month in 1960.

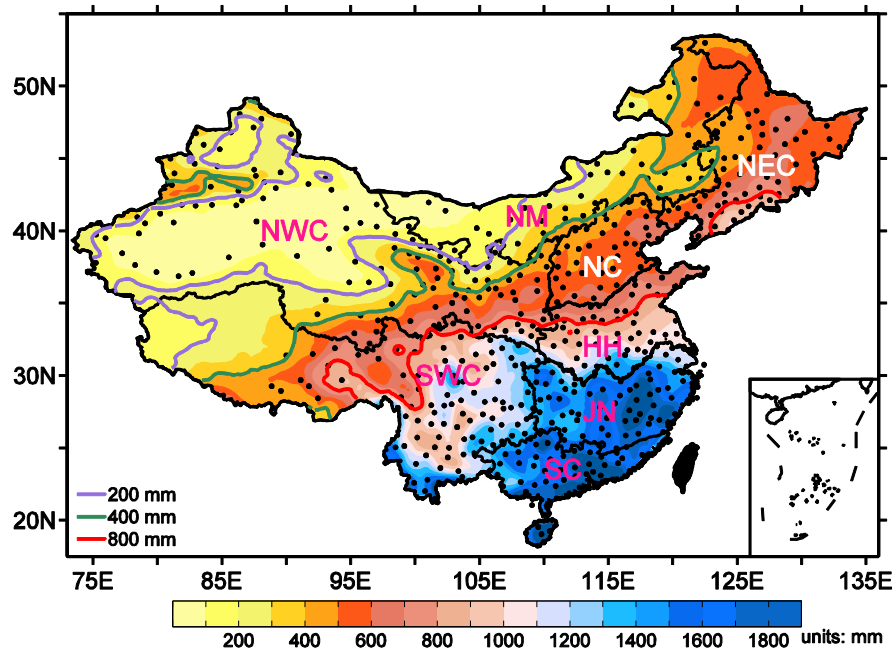

26
27

1 **Table 1.** Categorization of dry and wet grade according to the SPEI and the
2 corresponding cumulative probability relative to the base period.

Categorization	SPEI	Cumulative probability
Extremely dry	Less than -2	0.0228
Severe dry	-1.99 to -1.5	0.0668
Moderate dry	-1.49 to -1.0	0.1587
Normal	-1.0 to 1.0	0.5000
Moderate wet	1.0 to 1.49	0.8413
Severe wet	1.5 to 1.99	0.9332
Extremely wet	Larger than 2	0.9772
